ABSTRACT

Inlet-performance and external-drag-coefficient characteristics are presented without analysis. Effects are shown of variations of fuselage boundary-layer diverter profile, bleed-surface porosity, bleed-exit area, and inlet ramp, and lip angle.

SUMMARY

Wind-tunnel tests were conducted to measure the inlet-performance characteristics and the external-drag increments associated with various configurations and operating conditions for a 0.10-scale air-induction model of the YF-108A airplane. The effects of changes of the fuselage boundary-layer diverter profile, the porosity of porous bleed surfaces in the inlet, the area of the bleed-flow exits, and the angle of the inlet ramp and lip surfaces were investigated.

The tests were conducted at free-stream Mach numbers of 2.50, 2.76, and 3.00. The corresponding Reynolds numbers were  $2.8 \times 10^6$ ,  $2.4 \times 10^6$ , and  $2.1 \times 10^6$  per foot, respectively. The angle-of-attack range was from  $0^\circ$  to  $14^\circ$ , and the angle of sideslip range was from  $-5^\circ$  to  $+5^\circ$ .

Data from the tests are presented without analysis.

INTRODUCTION

The wind-tunnel investigation of a 0.10-scale air-induction model of the YF-108A airplane was conducted at the request of the Air Research and Development Command of the United States Air Force. The purpose of the tests was to obtain total-pressure-recovery, mass-flow-ratio, and flow-stability characteristics for various inlet configurations, and to measure drag increments associated with the various model configurations and operating conditions.

#### APPARATUS AND MODEL

The tests were conducted in the 8- by 7-foot test section of the Ames Unitary Plan wind tunnel.

The air-induction system model of the YF-108A airplane was furnished by North American Aviation, Incorporated. It consisted of a 0.10-scale reproduction of the forebody, the left-hand inlet, and the ducting to the face of the left-hand engine, plus a stub wing on the left side and a flow metering section of duct after the engine station. Photographs of the model installed in the wind tunnel and a drawing of the model are shown in figures 1 and 2(a).

The model was sting-mounted and included an integral strain-gage balance instrumented to measure chord force, normal force, and side force. Additional instrumentation included a 30-tube total-pressure rake and 6 static-pressure tubes at the simulated engine-face station; a calibrated flow metering nozzle; static-pressure orifices in each of four separate boundary-layer bleed plenum chambers; static-pressure orifices in the balance chamber, in the duct near the exit, and at the base around the duct exit; and a static-pressure transducer in the subsonic diffuser.

Total loads consisting of air loads on the external portion of the model ahead of section A-A in figure 2(a), and internal forces to the duct exit (station 157.75), were measured by the balance. Aft of section A-A, the model was shielded from external air loads. Inlet air flow was regulated by a motor-operated plug valve at the duct exit. Details of the engine-face rake are included in figure 2(b).

A schematic section drawing of the inlet is shown in figure 3. The inlet was rectangular and included a fixed,  $9^{\circ}$  initial compression ramp followed by a remotely controlled, hinged second ramp and throat assembly, and a remotely controlled hinged cowl lip which served as a third internal compression surface. Both the internal lip profile and the variable second ramp incorporated curved portions, as indicated in figure 3, to provide isentropic compression. The lip incorporated  $6^{\circ}$ , and the ramp  $5^{\circ}$ , of turning for this purpose.

The cross-sectional area variations of the duct from the lip hinge line to the total-pressure rake station are shown in figure 4 for several positions of the variable ramp and throat assembly. Forward of the lip hinge line, the area variation was a function of both lip angle and variable ramp angle.

Porous surfaces were utilized in the inlet and throat regions of the duct to bleed off the boundary layer formed on the duct walls and compression surfaces. Details of the supporting structure for the porous plates, and the size and shape of the porous-plate areas are shown in figures 5(a), 5(b), and 5(c). Details of the porous plate perforations are included in figure 6. The boundary-layer bleed flow was collected in four plenum chambers and was exhausted to the free stream through sonic exits. The porous areas and bleed exits are shown schematically in figure 6. Several porosities, or combinations of porosities, were used during the tests, and the bleed-exit areas were also varied. The porosity and bleed-exit configurations are defined in table I.

The inlet was displaced from the fuselage to provide a gutter for the fuselage boundary-layer air so that it would not be ingested into the inlet. The amount of the displacement (0.7 inch at the most forward point of the inlet, as shown in fig. 5(a)) was scaled from the actual airplane diverter height directly according to model scale, without regard to the difference between flight and wind-tunnel-test Reynolds numbers. The leading edge of the fuselage-boundary-layer diverter was located downstream from the most forward point of the inlet as shown in figure 5(a). Two boundary-layer diverter profiles were utilized during the tests; drawings of the two diverter profiles are shown in figure 7(a), and their configuration designations (convex and concave) are included in table I.

Two fuselage nose configurations were utilized in the tests. The second differed from the first only by the addition of a probe as shown in figure 7(b). Configuration designations for the two noses are included in table I.

## TESTS AND PROCEDURES

### Range of Test Variables

The tests were conducted at free-stream Mach numbers of 2.50, 2.76, and 3.00. The corresponding Reynolds numbers were approximately  $2.8 \times 10^6$ ,  $2.4 \times 10^6$ , and  $2.1 \times 10^6$  per foot, respectively. The angle-of-attack range was from  $0^\circ$  to  $14^\circ$ , and the angle-of-sideslip range was from  $-5^\circ$  to  $+5^\circ$ . The angles of attack and sideslip quoted herein are all nominal angles. The nominal angles of attack differ from the true angles by a maximum of  $\pm 0.1^\circ$  for a sideslip angle of  $0^\circ$  and by  $\pm 0.3^\circ$  for a sideslip angle of  $\pm 5^\circ$ . The nominal angles of sideslip differ from the true angles by a maximum of  $+0.3^\circ$  at nominal sideslip angles of  $\pm 5^\circ$ .

### Test Methods

For each test Mach number, model attitude, and inlet configuration, an initial, or transient, run was made during which no data were recorded, but inlet conditions were monitored to define the supercritical, critical, and subcritical inlet-flow regimes. For the transient runs, Mach number, model attitude, and variable-ramp angle were set at the scheduled values, the flow control plug valve was opened, and the inlet area was reduced by moving the hinged lip until supersonic flow was established in the inlet. Then the lip was moved to its scheduled position and the plug valve was slowly closed while the readings of the performance-indicating instrumentation were visually monitored. For the data-recording runs, the inlet-starting process was repeated and data were then recorded for selected settings of the plug valve. In most cases, data were recorded for several plug-valve settings yielding supercritical inlet flow, and for the setting yielding critical, or maximum pressure recovery. For selected cases, additional data were recorded for the subcritical, or unstarted, inlet-flow regime.

All pressure data were measured utilizing pressure transducers. The electrical output signals of the pressure transducers were recorded by an automatic sequential digital recorder along with the output signals from the balance strain gages and the digitized tunnel-condition and model-configuration information required.

### Reduction of Data

Computations of inlet-performance, total-drag coefficient, and internal-drag coefficient were accomplished utilizing automatic computing equipment.

The inlet-performance parameters computed and presented include average total-pressure ratio  $\bar{p}_{t_3}/p_{t_\infty}$  at the simulated engine-face station, flow distortion parameter  $\xi$ , mass-flow ratio at the engine station  $m_3/m_{th}$ , and mass-flow ratio at the inlet  $m_1/m_{th}$ . Average total-pressure ratio was computed as the average of the local total-pressure ratios for the 30 tubes of the total-pressure rake:

$$\frac{\bar{p}_{t_3}}{p_{t_\infty}} = \frac{\sum_{1}^{30} (p_{t_3}/p_{t_\infty})_{\text{local}}}{30}$$

The flow distortion parameter at the rake station was computed by the equation

$$\xi = \frac{(p_{t_3}/p_{t_\infty})_{\max} - (p_{t_3}/p_{t_\infty})_{\min}}{\bar{p}_{t_3}/p_{t_\infty}}$$

Mass-flow ratio at the engine station  $m_3/m_{th}$  was computed from static pressures measured at the calibrated flow metering nozzle aft of the simulated engine station by means of standard ASME nozzle flow equations. The mass-flow presented is based on the theoretical area of the free-stream tube captured by the inlet for each individual inlet configuration, angle of attack, and test Mach number. Thus, in terms of mass-flow ratio based on the fixed reference area  $A_{ref}$  of 0.130 square feet (the maximum capture area of the inlet for an angle of attack of  $0^\circ$  and a lip angle of  $0^\circ$ )

$$\frac{m_3}{m_{th}} = \left( \frac{m_3}{m_\infty} \right) \left( \frac{A_{ref}}{A_{th}} \right)$$

in which

$$m_3 = \rho_3 A_3 V_3 = \rho_\infty A_\infty V_\infty$$

$$m_\infty = \rho_\infty A_{ref} V_\infty$$

$$m_{th} = \rho_\infty A_{th} V_\infty$$

The conversion factor  $A_{ref}/A_{th}$  for each model attitude and configuration, which was based on theoretical shock-wave and flow-field patterns, was supplied by North American Aviation, Incorporated.

Total inlet mass-flow ratio  $m_1/m_{th}$  was computed as the sum of the engine mass-flow ratio and the four bleed mass-flow ratios:

$$\frac{m_1}{m_{th}} = \frac{m_3}{m_{th}} + \sum_1^4 \left( \frac{m}{m_{th}} \right)_{\text{bleed}}$$

Mass flow through each of the four bleed exits was computed based on total pressure for the bleed-flow plenum chambers, with sonic flow assumed through the exits. Static-pressure measurements on the plenum chamber walls were taken to be equal to plenum chamber total pressures.

The measured drag data were reduced to an external-drag coefficient  $C_{D_{ext}}$ , defined by the equation:

$$C_{D_{ext}} = C_{D_t} - C_{D_i}$$

The total-drag coefficient  $C_{D_t}$  represents the drag indicated by the balance with an adjustment included to correct the base pressure on the model to free-stream static pressure. No such adjustment was applied to the balance chamber pressures; visual monitoring showed that balance chamber pressure was a function only of Mach number, and not of model attitude, configuration, or internal flow characteristics. The drag results are intended to show increments, not absolute values.

## RESULTS

Inlet-performance characteristics and external-drag coefficients are presented without analysis in figures 8 through 34. (The chord-force gage of the balance malfunctioned during a portion of the tests; as a result, no drag data were available for certain model configurations and test conditions.) The figures are presented in five groups according to the model parameters being compared.

In the first group, figures 8 through 22, the results from a series of initial runs are plotted to show the effects of lip angle changes for selected ramp angles for each test Mach number and angle of attack for an angle of sideslip of  $0^\circ$ . Based on a comparison of these data, and with knowledge of previous tests of the inlet configuration by North American Aviation, Inc., the ramp and lip angle combinations tabulated in table II were selected for subsequent investigation of other configuration changes. In the first group of data, figures 21 and 22 are included to indicate the performance of the inlet with extreme settings of the ramp and lip. These represent the maximum and minimum settings which could exist as a result of a malfunction of the positioning controls in the actual airplane.

Correct values of the conversion factor  $A_{ref}/A_{th}$  were not available for the inlet with the ramp and lip in the extreme positions; the values tabulated in figures 21 and 22 were selected by North American Aviation, Inc.

In the second group of data, figures 23 and 24, the effect of the change of fuselage-boundary-layer diverter profile from convex to concave (see fig. 7(a)) is shown. Based on these data, the concave profile was used for the remainder of the tests.

In the third group of data, figures 25 and 26, the effects of changes of porosity of the boundary-layer bleed surfaces are shown, and in the fourth group of data, figures 27 through 31, the effects of changes in the bleed exit configurations are shown. The fifth group of data, figures 32 through 34, shows the effects of angles of sideslip from  $-5^{\circ}$  to  $+5^{\circ}$ .
